In Memoriam

Michael Corballis

Emeritus Professor Michael Corballis passed away while this volume on cerebral asymmetries—for which he had agreed to serve as volume editor—was being developed and he helped in its planning. Michael was a preeminent scholar in human cognitive neuroscience and neuropsychology. In a career that spanned seven decades, he made significant contributions to various research areas, including perception, attention, memory and mental time travel, language origins, recursive thought, and mind wandering. Central to his endeavors were the questions of human uniqueness and the role of hemispheric asymmetry in enabling and shaping the human mind.

Michael was born on September 10, 1936. His university education coincided with the foundation of academic departments of psychology in his native New Zealand, and with the evolution and expansion of neuropsychology internationally. He was among the first students to study psychology at Victoria University (Wellington) and the University of Auckland before moving to Montreal for his doctoral training at McGill University. Montreal had emerged as a hub of neuropsychologic thought, and the notion of grounding psychology in the anatomy and physiology of the brain inspired Michael's early interest in how cerebral lateralization might underlie asymmetries in perception and action.

Cerebral asymmetry remained a key focus after Michael returned to New Zealand in 1977. He was particularly interested in how apparently unrelated asymmetries might have common origins or lead to unexpected consequences. In *The Lopsided Ape* (1991), he reflected on the strong lateralization of both language and fine motor control, and advanced the hypothesis that language may have its origin in gesture rather than speech—an idea that would motivate much of his thinking for the next three decades.

Michael authored or coauthored more than 300 scientific articles, 14 books, and many commentaries, published reviews, and public-interest pieces. His status as a scholar was recognized through numerous fellowships and awards, including the New Zealand Order of Merit in 2002 and the Rutherford Medal from the Royal Society of New Zealand in 2016.

Aside from his prolific scholarship, Michael will be remembered for his urbane wit, humility, and generosity of spirit. He passed away peacefully on November 13, 2021, following a brief battle with cancer. He was predeceased by Barbara, his wife of 58 years, and is survived by his sons Paul and Timothy, and three granddaughters, Simone, Natasha, and Lena.

Abstract

The cerebellum is a subcortical structure tucked underneath the cerebrum that contains the majority of neurons in the brain, despite its small size. While it has received less attention in the study of brain asymmetries than the cerebrum, structural asymmetries in the cerebellum have been found in cerebellar volume that mirror cerebral asymmetries. Larger cerebellar structures have been reported on the right compared to the left, either for the whole cerebellar hemisphere or the anterior part of the cerebellum, with the latter accompanied by a left increase in the posterior cerebellum. Cerebellar asymmetries are considered evolutionary recent and have been observed prenatally and in early development. Both asymmetries in anterior–posterior divisions and specific lobules have been linked to handedness and cognitive abilities, in particular language. Functional lateralization in the cerebellum varies across motor and cognitive functions, with language activation predominantly localized in the right hemisphere, contralateral to cerebral activation. Meanwhile, working memory and executive functions are not lateralized to one hemisphere. New neuroimaging methods and resources, including a symmetric functional atlas of the cerebellum that enables precision mapping, open novel avenues for exploring cerebellar asymmetries and answering questions about the developmental timeline, relationships to behavior, and clinical relevance.

INTRODUCTION

The cerebellum, or “little brain,” is a small structure situated underneath the much larger cerebrum. Despite only making up 10% of the total brain mass, the cerebellar cortex holds 80% of all neurons (Azevedo et al., 2009) and when fully unfolded has a surface area of 78% of the neocortex (Sereno et al., 2020). The cerebellum supports a multitude of functions, including motor, executive, social, linguistic, and emotional processes. Studies of functional lateralization, particularly of higher-order cognitive functions such as language, often prioritize the cerebrum over the cerebellum. Similarly, studies of structural asymmetries have largely focused on the cerebrum, leaving many questions about cerebellar structural and circuitry asymmetries unanswered. This is partially driven by difficulties in imaging the cerebellum and a lack of tools necessary for careful investigations of cerebellar functional asymmetries. Still, studies to date provide a picture of cerebellar organization that is broadly symmetric, but includes fine hemispheric differences, some of which mirror cerebral asymmetries. Here, we review asymmetries in cerebellar structure, function, and neurochemistry. We also consider

technical challenges in studying cerebellar asymmetries and outline recent advances addressing these limitations, enabling future in-depth studies of cerebellar asymmetries.

STRUCTURAL ASYMMETRIES

Broad cerebellar structure

The cerebellum consists of two hemispheres that are connected through the vermis, a worm-like midline structure. The cerebellum sits within the posterior fossa and connects to the brainstem via three pairs of peduncles: the superior, middle, and inferior peduncle. The inferior cerebellar peduncle and middle cerebellar peduncle contain mainly afferent projections to the cerebellum from the spinal cord and the cerebrum, respectively. The inferior peduncle also contains efferent projections from the cerebellum to the spinal cord. The superior peduncle primarily transports efferent fibers from the cerebellum, projecting to the cerebrum. Cerebellar afferents and efferents cross over to the contralateral cerebral hemisphere in the brainstem. In general, the cerebellum therefore connects to the contralateral cerebral hemisphere and is concerned with inputs from the ipsilateral side of the body.

The tightly folded cerebellar cortex is commonly divided along broad anatomic divisions, the fissures, into 10 lobules and denoted I–X according to the Larsell nomenclature (Larsell and Jansen, 1973; Schmahmann et al., 2000). Lobules I–V form the anterior cerebellum, lobules VI–IX the posterior cerebellum, and lobule X forms the flocculonodular lobe of the cerebellum. Because lobules VII and VIII are the two largest lobules in the human cerebellum (Diedrichsen and Zotow, 2015), many studies split them into two sections (VIIA and VIIB, as well as VIIIA and VIIIB), and lobule VIIA is split again into Crus I and Crus II.

Neuroimaging studies have identified gross asymmetries in cerebellar structure in children (Holland et al., 2014) and across the adult lifespan (Herve et al., 2006; Fan et al., 2010; Bernard and Seidler, 2013; Kang et al., 2015). While some found an overall larger right hemisphere of the cerebellum (Herve et al., 2006; Fan et al., 2010; Kang et al., 2015), others reported this volume increase on the right for only some cerebellar lobules (Kavaklioglu et al., 2017). However, some studies fail to show any structural asymmetries in the cerebellum (Gocmen-Mas et al., 2009; Ertekin et al., 2013). The earliest report of cerebellar structural asymmetry divided the cerebellum into an anterior and a posterior section according to coronal MRI slices acquired in 15 right-handed and 8 left-handed participants (Snyder et al., 1995). The authors found that in the anterior cerebellum, the right hemisphere was significantly larger than the left, whereas in the posterior cerebellum the left was bigger than the right. A similar pattern had previously been described for the neocortex (LeMay, 1976), with right anterior structures (e.g., frontal pole) extending more anteriorly and left posterior structures (e.g., occipital pole) protruding more posteriorly. This is despite the cerebellum primarily projecting to the contralateral cerebral hemisphere, which could suggest an opposite pattern of asymmetry.

HANDEDNESS

When first reporting cerebellar structural asymmetry (Snyder et al., 1995), also found a link to handedness: while all 23 participants showed an overall similar asymmetry pattern, it was more pronounced in right-handed people. A later study of 19 monozygotic female adult twins confirmed some of the structural asymmetries in the cerebellum, with the anterior cerebellum (lobules I–V) being larger on the right, but near symmetry in the posterior cerebellum (lobules VI–VIIIB) (Rosch et al., 2018). The anterior cerebellar asymmetry was stronger in right-handed than left-handed twins, potentially reflecting an experience-dependent maintenance of higher growth rates in the right hemispheric cerebellum. However, differences in the definition of regions of interest between the first report, where sections were divided by coronal slice, and the more precise definition in the later study based on a lobular atlas (Diedrichsen, 2006), make a direct comparison difficult. Furthermore, the purported relationship between cerebellar asymmetry and handedness was not replicated in a large-scale study of 2226 participants (Kavaklioglu et al., 2017), but a recent investigation of over 37,000 participants

associated handedness with whole-brain asymmetry patterns that included the cerebellum. Directly comparing left- and right-handed participants revealed that right-handers showed larger lobules VIIIA and VIIIB in the right cerebellar hemisphere and larger Crus I and Crus II in the left cerebellar hemisphere (Saltoun et al., 2023).

EVOLUTIONARY AND DEVELOPMENTAL STUDIES

Cerebellar structural asymmetry seems to have emerged recently in evolution, as it is only observed in modern humans—*Homo sapiens*—but not in *Homo erectus* or *Homo neanderthalensis* (Zhang and Wu, 2021). This is in contrast to cerebral asymmetries, which emerged earlier, appearing already in *Homo erectus* and *Homo neanderthalensis* (Holloway and De La Costelareymondie, 1982; Li et al., 2018).

During gestation, the cerebellum grows more quickly than any other brain region, increasing 34-fold from weeks 18–39. Early in gestation, the left cerebellar hemisphere is larger than the right, but the right shows an accelerated growth curve, nearly overtaking the left by week 39 (Andescavage et al., 2017). During the first 3 months after birth, the cerebellum again shows the fastest growth, more than doubling in size (Holland et al., 2014). During this time, the right cerebellar hemisphere is larger than the left. Cerebellar asymmetry does not depend on sex in the first 3 months of life (Holland et al., 2014), though there is some evidence for an interaction between sex and cerebellar structural asymmetries in children (Isiklar et al., 2023) and young adults (Fan et al., 2010).

RELATIONSHIP WITH MOVEMENT, LANGUAGE, AND COGNITION

Several studies have related cerebellar structural asymmetries to language, motor, and cognitive functions. Neonatal whole-cerebellar asymmetry has been found to predict later language skills (Vassar et al., 2020), with more cerebellar asymmetry being linked to lower language scores as assessed with the Bayley Scales of Infant-Toddler Development-III (Bayley, 2006). However, cerebellar asymmetries in this study were based on rating scale assessments by radiologists, which differs substantially from the quantitative techniques used in previous studies (Holland et al., 2014; Andescavage et al., 2017). In 10-year-old children, whole cerebellar volume showed no association with language content, but correlated positively with right gray matter volume in Crus I/Crus II (Stipdonk et al., 2021). In a cohort of 48 autistic and non-autistic boys aged 6–13 with and without language impairment (autistic language impairment or specific language impairment), only those with impaired language function showed leftward lobule VIIIA asymmetry, irrespective of autism diagnosis. Non-impaired boys showed larger right lobule VIIIA volume, and language performance correlated with lobule VIIIA asymmetry across groups, with increased volume on the right relating to higher language scores (Hodge et al., 2010). Decreased cerebellar volume in the right hemisphere of 32 children with cerebellar malformations (aged 1–6) has been linked to impaired expressive language, as well as cognitive and motor impairments (Bolduc et al., 2012).

In adults, working memory task performance has been found to positively correlate with gray matter volume in left Crus I (Ding et al., 2012), and improved timing in musical performance has been associated with smaller right lobule VI volume (Baer et al., 2015). Meanwhile, increased volume of the cerebellar cortex was associated with mild cognitive impairment in a study of 400 randomly selected older adults (aged 64–70) (Cherbuin et al., 2010). Asymmetric gray matter reductions and torque have also been linked to neuropsychiatric disorders such as autism spectrum disorder, developmental dyslexia (Stoodley, 2014), and schizophrenia (Szeszko et al., 2003).

Cerebellar damage from injury, stroke, or degeneration has previously been shown to cause, in addition to the classic motor impairments, a range of non-motor symptoms. These include language deficits, anagrammatism, executive function deficits, and social and affective impairments that were termed the “Cerebellar Cognitive Affective Syndrome” (Schmahmann and Sherman, 1998). To our knowledge, there are so far no reports of Cerebellar Cognitive Affective Syndrome manifesting as lateralized to a particular hemisphere, although functions that belong to the symptom set of the syndrome certainly appear lateralized (see section *Task-based asymmetries*). Notably, cognitive symptoms after cerebellar damage in adults appear milder than in young children (Glickstein, 1994; Fabbro et al., 2004; Ronconi et al., 2017) and often result in a decrease in function rather than a full loss of it (Olson et al., 2023). For example, cerebellar damage to right Crus I/II appears to not result in aphasia or absence of speech, but in dysarthria (Ackermann, 2008; Stoodley et al., 2016) or agrammatism (Silveri et al., 1994).

Deep cerebellar nuclei

The cerebellar white matter envelops the deep cerebellar nuclei, which lie close to the midline in each hemisphere and receive the output generated from the cerebellar cortex. The deep cerebellar nuclei then project to the brainstem nuclei and the cerebral cortex via the thalamus. Only the flocculonodular cerebellar cortex, lobule X, deviates from this by projecting directly to the vestibular nuclei in the brainstem. As such, the deep cerebellar nuclei and the vestibular nuclei are the sole transmitters of the output from the cerebellum. The deep cerebellar nuclei include in each hemisphere along the medial-to-lateral axis, the dentate nucleus, the interpositus (consisting of globose and emboliform nuclei), and the fastigial nucleus.

Few neuroimaging studies have examined the structure of deep cerebellar nuclei due to their small size and their near invisibility in standard T1-weighted anatomic images (Diedrichsen et al., 2011). Only susceptibility-weighted images, which are not part of standard MRI protocols, provide suitable contrast for localizing the deep cerebellar nuclei, as these images are sensitive to their high iron content. A first volumetric comparison of left and right dentate nuclei reported increased volume on the right in 9 of 10 examined participants (Deoni and Catani, 2007), though this was not replicated in a later study of 23 participants (Diedrichsen et al., 2011). In postmortem sections of human

brains, visual comparison of the dentate ribbon revealed left–right differences in the folding pattern of a single case, but no systematic differences.

Cytoarchitecture

While the cerebral cortex is dividable according to its cytoarchitecture, the cerebellar cortical makeup is generally remarkably uniform. The single output cell of the cerebellar cortex is the Purkinje cell. Each Purkinje cell receives inputs via two streams. First, they receive multiple inputs from multiple parallel fibers. Parallel fibers arise from the densely packed granule cells. Granule cells receive information via mossy fibers that originate in the spinal cord, medulla oblongata, and most massively from the pontine nuclei. The majority of axons exiting the neocortex for the brainstem either project directly to the pons or send a collateral there, which projects onto the granule cells (Tomasch, 1969). Granule cells then innervate Purkinje cells via parallel fibers. Second, each Purkinje cell receives input from a single climbing fiber, originating in the inferior olivary nucleus, though a single climbing fiber branches to innervate one to seven Purkinje cells.

Detailed descriptions of the cerebellar circuit have led to the development of the Marr-Albus-Ito model of cerebellar function (Eccles, 1967; Marr, 1969; Albus, 1971; Ito and Kano, 1982). This model is based on the convergence of the two input types at the Purkinje cell. First, the many inputs from parallel fibers are proposed to represent a detailed context. Second, the single climbing fiber input is proposed to represent an error, or “teaching” signal. When a Purkinje cell receives climbing fiber activation (error signal) shortly after activation of a set of parallel fibers (context), then the synaptic weights of this particular set of parallel fibers change through long-term depression (Ito and Kano, 1982). When this set of parallel fibers is activated again at this Purkinje cell, the Purkinje cell firing is reduced compared to before. The change in Purkinje cell firing leads to a change in behavior, a change in output to the deep cerebellar nuclei, and suppression of the climbing fiber input (Medina and Lisberger, 2008).

The Marr-Albus-Ito model explains a wealth of experimental data, particularly in the motor domain, and has been highly influential. However, recent studies cast doubt on a universal learning principle within the cerebellar cortex by painting a more complex picture of cerebellar circuitry (Beckinghausen and Sillitoe, 2019; Fujita et al., 2020; Busch and Hansel, 2023). In humans, Busch et al. (Busch and Hansel, 2023) showed in sagittal slices of three postmortem human brains that only 4% of human Purkinje cells have the stereotypic single dendritic branch, while 96% show a multibranching dendritic branch that bifurcates into multiple primary dendrites close to the neuron body. In mice, 15% of multibranching Purkinje cells also receive multiple climbing fiber inputs to the different dendritic branches, and some branches seemed to have locally distinct functional responses to whisker stimulation. These results show a clear divergence from the purported regularity of the cerebellar circuitry. The authors also described an anterior-to-posterior gradient in dendritic branching patterns, where the majority of Purkinje cells in lobules I–VI had

normative, single-branched dendrites and the multibranched dendrites occurred in the majority of lobule VII–X. However, left–right asymmetries in Purkinje cell branching could not be detected, as the investigation focused on sagittal slices of the mid-section of only one hemisphere, precluding a between-hemispheric comparison.

Summary

Studies of structural asymmetries in the cerebellum have largely focused on the cerebellar cortex or overall cerebellar volume rather than the cerebellar nuclei, due to its relative accessibility in neuroimaging data. Generally, studies find rightward asymmetry in the cerebellum, with increased cerebellar volume on the right anterior cerebellum and increased left volume in the posterior cerebellum. Cerebellar asymmetries seem to be evolutionary recent and appear before birth. Some links with handedness, cognitive functions, and clinical diagnosis have been reported, although little consensus has been found. This may in part be driven by differences in analysis methods and techniques used to assess cerebellar asymmetry. Some studies have divided the cerebellum along the anterior-to-posterior axis for asymmetry analysis (Snyder et al., 1995), others group lobules into cerebellar zones (Bolduc et al., 2012; Rosch et al., 2018) or use ratings from radiologists to assess cerebellar asymmetry (Stipdonk et al., 2021). Establishing consensus on cerebellar asymmetry across the heterogeneous literature is therefore difficult.

As tools for cerebellar segmentation and atlases for cerebellar parcellation have been developed, most studies now parcellate the cerebellum along lobular boundaries (Fan et al., 2010; Bernard et al., 2015; Kavaklioglu et al., 2017; Isiklar et al., 2023; Saltoun et al., 2023) based on a probabilistic group atlas of cerebellar lobules (Diedrichsen, 2006). This makes comparing results across neuroimaging studies easier. However, most researchers are interested in linking observed asymmetries to cerebellar function, relying on the assumption that different cerebellar-dependent functions can be localized to different lobules. Mapping cerebellar activity across motor and cognitive domains revealed this is not the case (King et al., 2019). Indeed, cerebellar activity usually spans several lobules, and one lobule often contains multiple functional regions. Future studies of structural asymmetry in the cerebellar cortex should therefore use symmetric regions of interest that capture functional regions when attempting to link structural asymmetries to function. For a discussion of recent advances in this realm, see section [Technical considerations for studying cerebellar lateralization](#).

FUNCTIONAL LATERALIZATION

The cerebellum has traditionally been associated with motor function, though neuroimaging studies show cerebellar activity during a broad range of behavioral tasks, including those probing language (Petersen et al., 1989), social cognition (Van Overwalle et al., 2015), attention (Allen et al., 1997), and working memory (Marvel and Desmond, 2010). While the cerebellum has been researched extensively in motor control, the study of the cerebellar role in higher-order cognitive functions such as language is in its relative infancy.

Task-based asymmetries

A function is considered lateralized if it engages one hemisphere of the brain more than the other, of which language function is a prime example. Right-lateralization of language activation in the cerebellum, mirroring left lateralization in the cerebrum, is well established (Amunts et al., 1996; Stoodley and Schmahmann, 2009; Fedorenko et al., 2010; Haberling and Corballis, 2016; LeBel and D’Mello, 2023). Though most language studies do not focus on the cerebellum or do not cover the cerebellum during data acquisition or analysis, there are early reports of functional lateralization in the right cerebellum during language processing (Petersen et al., 1989; Raichle et al., 1994).

Using positron emission tomography, Petersen et al. (Petersen et al., 1989) were the first to show clear lateralized cerebellar activation during language processing, even when motor demands were accounted for. Subsequent studies confirmed right cerebellar activation during language processes such as semantic retrieval and prediction (Fiez et al., 1996; Moberget and Ivry, 2016; Lesage et al., 2017).

A meta-analysis of task-based fMRI studies showed that language activity primarily occurs in the right cerebellum in lobule VI, Crus I/Crus II as well as vermal lobule VIIA (Stoodley and Schmahmann, 2009). On the other hand, left-lateralized activation was found primarily for spatial tasks, located in lobule VI. However, both language and spatial tasks showed some weaker, but consistent bilateral activation, occupying a small cluster in opposite lobule VI.

To examine the relationship between language lateralization in the cerebellum and neocortex, Wang et al. (Wang et al., 2013) analyzed fMRI data acquired while participants performed a semantic decision task. In the cerebellum, participants showed strong language lateralization in the right Crus I/Crus II and in the cerebrum, in the left prefrontal cortex. Language activity lateralization in the cerebellum was correlated with language lateralization in the cerebrum: right cerebellar task lateralization correlated with left cerebral task-based language lateralization. In line with lateralization of language and spatial function, patients with left-sided cerebellar lesions showed larger impairments in attention and visuospatial tasks, but not language, fluency, or motor function (Starowicz-Filip et al., 2021). Right-sided cerebellar lesions, on the other hand, led to impaired language and verbal fluency, but also general cognitive deficits, including memory, attention, and visuospatial functions (Silveri et al., 1994; Marien et al., 1996; Leggio et al., 2000; Marien et al., 2000). A detailed analysis of cerebellar lateralization was recently provided by a voxel-wise comparison of functional profiles across 417 tasks probed in seven fMRI datasets (Nettekovén et al., 2024) (1A). Social-linguistic-spatial regions located in Crus I and Crus II (2A) showed low correlations of functional profiles, indicating strongly lateralized functional responses. On the left, these regions activated while viewing social and emotional stimuli, whereas the right regions showed far less activity in those tasks. On the right, the cerebellum responded primarily to tasks involving linguistic information, such as a word reading and theory of mind story reading task or a verb generation task. In contrast, cerebellar working memory regions in lobules VI and VII

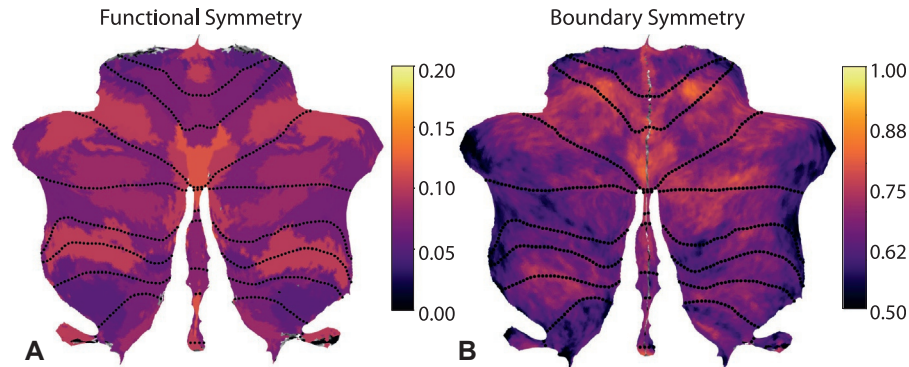

Fig. 23.1. Functional lateralization and boundary symmetry of cerebellar functional regions. Functional symmetry calculated as the correlations between the functional responses of anatomically corresponding voxel in the left and right hemispheres, averaged across participants and within each functional region (A) reveals bilateral response profiles of multiple demand regions and lateralized responses of social-linguistic-spatial regions. Boundary symmetry calculated as the correlations of the probabilistic voxel assignments between the symmetric and asymmetric versions of the atlas (B) shows symmetric boundaries in the motor regions, and asymmetric boundaries in social-linguistic-spatial regions. Reproduced from Nettekoven C, Zhi D, Shahshahani L, et al. (2024). A hierarchical atlas of the human cerebellum for functional precision mapping. *Nat Commun* 15: 8376. <https://doi.org/10.1038/s41467-024-52371-w>.

showed largely bilateral responses (Fig. 23.1A), as indicated by highly correlated functional profiles across tasks. This was despite the variety of executive function and working memory tasks in the task set, including those probing verbal working memory. Hence, while there might be some lateralization of working memory and executive function, the majority of tasks activate cerebellar working memory regions bilaterally.

Neuroimaging studies of motor and sensory tasks show sensorimotor homunculi on each side of lobules III–VI and lobule VIII (Stoodley and Schmahmann, 2009). Cerebellar activity is largely confined to the hemisphere ipsilateral to the moving effector (Saadon-Grosman et al., 2022), but bilateral for tongue and eyes (Buckner et al., 2011; Nettekoven et al., 2024). A voxel-wise comparison of the functional profiles confirmed this pattern of lateralization in cerebellar motor regions. The left and right cerebellar hand regions (M3) show low correlations of functional profiles (Fig. 23.1A). Finally, activity in the oculomotor vermis, responsible for eye movements and saccades, showed strongly bilateral responses. Therefore, while some functions are clearly lateralized in the cerebellum, such as language and social cognition, others are consistently bilateral like working memory and executive function, or exhibit laterality that appears effector-dependent such as motor functions.

In addition to having different functional profiles, boundaries between functional regions themselves can be asymmetric. The recent development of a symmetric functional atlas of the cerebellum (see section Technical considerations for studying cerebellar lateralization) allowed for the first systematic comparison of boundary symmetry in the cerebellum (Nettekoven et al., 2024). Examining the correspondence between the symmetric and asymmetric version of the atlas (Fig. 23.1A and B) across the different regions revealed that regions involved in movement and working memory functions have highly symmetric boundaries, i.e., their boundaries fall into the same place on the left and right. Among the motor regions, the oculomotor vermis M1 and the hand region M3 (Fig. 23.1A) fall particularly similar in left and right cerebellar hemisphere. Meanwhile, the social-linguistic-

spatial regions have more dissimilar region boundaries between left–right region pairs, indicated by the low overall boundary symmetry in social-linguistic-spatial regions (Nettekoven et al., 2024).

Resting-state connectivity asymmetries

fMRI data acquired at rest has been used to quantify cortico-cerebellar functional connectivity and examine cerebellar lateralization in the context of cerebral lateralization (O’Reilly et al., 2010; Buckner et al., 2011; Wang et al., 2013; Wang et al., 2014). In the cerebellum, resting-state fMRI data from 1000 participants demonstrated an approximately homotopic map of cerebral connectivity networks (Buckner et al., 2011). Here, each cerebellar voxel was assigned to the cerebral resting-state network its resting-state time course correlated with the most (Buckner et al., 2011). Consistent with viral tracing studies in monkeys demonstrating that cerebral cortical areas project to the contralateral cerebellum (Kelly and Strick, 2003), cortico-cerebellar connectivity is strongest between contralateral cerebellar and cerebral regions, particularly in the motor regions (Krienen and Buckner, 2009; O’Reilly et al., 2010; Buckner et al., 2011). Resting-state and task-based fMRI data demonstrated a somatomotor map of the body including foot, hand, and tongue representations in the anterior cerebellum (Buckner et al., 2011). The task-based maps revealed that lateralization of somatomotor representations in the cerebellum varies with body part. While tongue representation is bilateral, consistent with the bilateral nature of the performed tongue movement, right foot and hand representations are lateralized, with right hand activation showing the strongest lateralization. Whether this lateralization depends on handedness to our knowledge has so far not been investigated.

Resting-state connectivity between ipsilateral and contralateral corticocerebellar regions followed a similar pattern: Hand and foot regions showed much stronger coupling contralaterally than ipsilaterally, whereas tongue regions showed no difference between ipsi- and contralateral connectivity. This echoes observations for the cerebral cortex showing the lowest inter-hemispheric connectivity

between the two hand regions and the two foot regions, and high coupling for left and right tongue representations (Thomas Yeo et al., 2011).

Technical considerations for studying cerebellar lateralization

Studies of functional lateralization often necessitate defining regions of interest in the left and right hemispheres, which are matched in location and size to control for spatial differences in signal-to-noise ratio (Yan et al., 2023). Most researchers have used anatomic subdivisions into different lobules (Schmahmann et al., 2000; Diedrichsen et al., 2009) to define regions of interest, taking advantage of the anatomic symmetry of lobules. However, lobular boundaries do not reflect functional boundaries in the cerebellum (King et al., 2019), rendering them unsuitable for functional lateralization studies. Recently, a symmetric functional atlas has been developed, using a machine learning model that learns the functional organization of the cerebellum using over 100 participants across seven fMRI studies (Nettekovén et al., 2024) (Fig. 23.2A and B). The model was constrained to learn corresponding symmetric regions, while the functional responses of the matching regions could vary between the left and right hemispheres (Zhi et al., 2025). The symmetric group atlas captured functional organization 5% less accurately than the asymmetric group atlas, which represents a small trade-off between the validity of the region boundaries and practical utility for lateralization studies.

The cerebellum poses many challenges to functional neuroimaging, but the study of cerebellar functional lateralization holds promise for answering fundamental questions about brain asymmetries. Though it suffers from lower signal-to-noise ratio, the sources of noise in the cerebellum differ from those in the cerebrum, driven by different anatomic and technical constraints. By contrasting and comparing cerebral and cerebellar asymmetries, some consensus on brain asymmetries can be established, independently of the different noise sources (Wang et al., 2013).

Summary

The cerebellum shows clear functional lateralization for some, but not all, motor and cognitive functions. Language activation is largely located in the right cerebellar hemisphere, contralateral to cerebral activation. Cerebellar functional lateralization appears to be linked to cerebral functional lateralization, handedness, and lateralization of language function. However, difficulties in aligning left and right cerebellar regions of interest for studies of functional lateralization have hindered progress in this line of research. The recent development of new methods and resources for the study of cerebellar lateralization could pave the way to more precise studies of functional asymmetries in the cerebellum.

NEUROCHEMICAL ASYMMETRIES

Few studies of neurochemical asymmetries in the cerebellum exist, primarily due to the technical challenges in measuring neurochemicals from the human cerebellum *in vivo*. Neurochemicals in the brain can be measured noninvasively using magnetic resonance spectroscopy (MRS). However, the use of MRS in the cerebellum is impeded by the close proximity of the cerebellum to two large sources of noise: the brainstem on the anterior side and the neck on the posterior side. The fat tissue in the neck emits a signal over 100 times stronger than brain metabolites (Rothman et al., 1993) and when MRS measurements are collected close to this fatty tissue, imperfect slice selection pulses can lead to lipid contaminations of the measured spectrum (Kreis, 2004). Placing an MRS voxel in the small, curved cerebellar hemispheres at a sufficient distance from fat tissue while maximizing the gray matter content of the voxel is therefore difficult. Similarly, areas adjacent to the brainstem can suffer from high levels of physiologic noise, driven by the cardiac and respiratory cycles (Brooks et al., 2013), which induce field inhomogeneities and reduce the quality of the MRS spectra. However, with the advent of high-field imaging and improved shimming techniques for reducing field

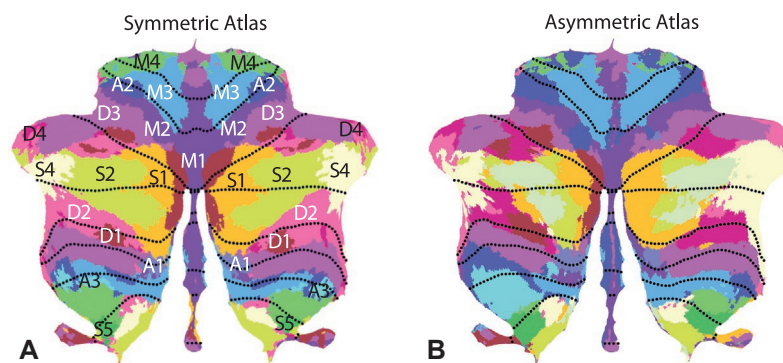

Fig. 23.2. Symmetric functional atlas of the cerebellum allows investigations of lateralization. (A) Functional atlas of the cerebellum with 32 symmetric regions. (B) Functional atlas of the cerebellum with 32 corresponding asymmetric regions. The atlas (A and B) across the different regions revealed that regions involved in movement and working memory functions have highly symmetric boundaries, i.e., their boundaries fall into the same place on the left and right. Among the motor regions, the oculomotor vermis M1 and the hand region M3 (A) fall particularly similar in the left and right cerebellar hemispheres. Meanwhile, the social-linguistic-spatial regions have more dissimilar region boundaries between left–right region pairs, indicated by the low overall boundary symmetry in social-linguistic-spatial regions (Nettekovén et al., 2024). Reproduced from Nettekoven C, Zhi D, Shahshahani L, et al. (2024). A hierarchical atlas of the human cerebellum for functional precision mapping. *Nat Commun* 15: 8376. <https://doi.org/10.1038/s41467-024-52371-w>.

inhomogeneities, there have been some investigations of cerebellar neurochemistry and their hemispheric differences.

In a first investigation study of cerebellar neurochemistry, Rae et al. (Rae et al., 1998) examined hemispheric differences in cerebellar neurochemical ratios in 14 dyslexic men and compared them to 15 male controls. In the right cerebellum of dyslexic men, the authors found decreases in the ratio of choline (Cho) to *N*-acetylaspartate (NAA), a commonly used reference metabolite (Bachtiar and Stagg, 2013) due to the high concentrations of NAA in the brain. Dyslexic men also showed significantly lower levels of creatine (Cr)/NAA in the right cerebellum compared to controls and a significant hemispheric difference in Cr/NAA concentration, whereas controls showed no hemispheric difference. The dyslexic group showed contralateral alterations in the neocortex. In the left temporoparietal lobe, dyslexic men showed significantly reduced Cho/NAA levels compared to controls and compared to their right Cho/NA levels, where controls showed equal levels.

Although motor impairments in dyslexia have been linked to a role of the cerebellum in this developmental disorder (Nicolson et al., 1995), in line with the hypothesis that cerebellar dysfunction could manifest in incoordination of eye movements during reading, no association between cerebellar neurochemistry and handedness or performance on a peg-board test was found. Nevertheless, the study provided compelling evidence for asymmetrically altered levels of cerebellar neurochemicals in dyslexia.

Tracking cerebellar neurochemical concentration over time in healthy participants has been of recent interest as a means to understanding cerebellar plasticity in healthy human function. In particular, the major inhibitory neurotransmitter γ -aminobutyric acid (GABA) has been suggested to play a fundamental role in cerebellar plasticity, since it signals information from the sole output neuron of the cerebellar cortex, the Purkinje cell, and has been implicated in parallel fiber synaptic plasticity (Orts-Del'Immagine and Pugh, 2018). Jalali et al. (Jalali et al., 2018) were the first to probe

the responsiveness of the GABAergic system in the cerebellum and attempt to link it to individual differences on a task probing motor adaptation, where the cerebellum plays a key role (Diedrichsen, 2005; Graydon et al., 2005; Miall and Jenkinson, 2005). Based on previous work linking anodal transcranial direct current stimulation (tDCS) to reductions in GABA in the primary motor cortex and motor learning (Stagg et al., 2009; Kim et al., 2014), the authors tested for changes in GABA concentration in the right cerebellar hemisphere in response to right cerebellar tDCS and attempted to link these changes to adaptation performance. There was no significant change in GABA, but exploratory analyses revealed a correlation between late adaptation and stimulation-driven GABA decrease. The authors noted as one of the reasons for the lack of GABA change in response to adaptation the long MRS acquisition time of 25 min, which might have rendered transient changes in GABAergic levels undetectable.

In a subsequent investigation of GABA changes occurring in the cerebellum during adaptation, MRS measurements were acquired in 9-min blocks from both the left and right cerebellar hemispheres (see Fig. 23.3A) while participants performed a right-hand adaptation task in the scanner (Nettekoven et al., 2022). Isolating adaptation-driven GABA changes revealed diverging GABA concentration at the right and left cerebellar nuclei (see Fig. 23.3B) with left cerebellar GABA increasing and right cerebellar GABA decreasing. The extent of the early GABA change at the right cerebellar nuclei showed a relationship with adaptation performance (Fig. 23.3C). Those participants who showed greater GABA decrease also adapted better. This relationship was specific to right cerebellar GABA change and adaptation, as there was no relationship with left cerebellar GABA change. Though these results present the first evidence for lateralized neurochemical signatures of cerebellar-dependent motor behavior of the right hand, further MRSI studies are necessary to provide a full picture of cerebellar neurochemistry and its role in motor and non-motor functions.

Fig. 23.3. Asymmetric neurochemical changes at cerebellar nuclei during adaptation. Magnetic resonance spectroscopic imaging (MRSI) can be used to quantify the major inhibitory neurotransmitter GABA in several cerebellar voxels in vivo, as shown for a representative participant (A). Isolating neurochemical changes in response to righthand adaptation reveals diverging GABA at the left and right cerebellar nuclei (B) and a relationship between early GABA change at the right cerebellar nuclei and adaptation performance (C). Reproduced from Nettekoven C, Mitchell L, Clarke WT, et al. (2022). Cerebellar GABA change during visuomotor adaptation relates to adaptation performance and cerebellar network connectivity: a magnetic resonance spectroscopic imaging study. *J Neurosci* 42: 7721–7732.

CONCLUSIONS

Asymmetries have been documented in the structure, function, and neurochemistry of the cerebellum. Functional asymmetries are largely confined to the cerebellar hemisphere contralateral to the cerebrum, while broad structural asymmetries show the same pattern in the cerebellum and cerebrum. The extent of cerebellar asymmetries has also been linked to handedness and performance on lateralized functions, such as language. However, technical challenges in measuring and analyzing cerebellar asymmetries have so far hindered thorough studies of cerebellar lateralization. Hence, several questions regarding the function and clinical consequences of cerebellar asymmetries remain open. For example, does the development of functional asymmetries in the cerebellum precede, parallel, or follow the development of corresponding cerebral functional asymmetries? To what extent does cerebellar asymmetry vary with biologic factors such as age, sex, handedness, and heredity? And what is the relationship between cerebellar asymmetry and disorders that involve the cerebellum such as schizophrenia, and how can we use this knowledge to improve diagnosis and treatment? The development of specialized imaging techniques and new tools for the study of the cerebellum now opens the opportunity to answer these questions.
